

NOTES FOR GENERALISING THE

RECURSIVE PATH ORDERINGS.

SAM KAMU - JEAN-JACQUES LEVY

① FUNCTIONALS ON ORDERINGS:

We would like to prove that the following Ackermann system is neitherian.

$$\begin{cases} A(sx, sy) \rightarrow A(x, A(sx, y)) \\ A(sx, o) \rightarrow A(x, so) \\ A(o, x) \rightarrow sx \end{cases}$$

With the usual recursive path ordering, this is not possible because $\{sx, sy\} \not\rightarrow \{x, A(sx, y)\}$. Here some lexicographic ordering seems necessary. And surely $(sx, sy) \geq_{lex} (x, A(sx, y))$. However, they are not sufficient since this will work too with

$$A(sx, sy) \rightarrow A(x, A(sx, sy)).$$

But one property of simplifications is that:

$t > u = f t$ implies $t > u_i$ for all arguments u_i . Hence, what could work is bounded lexicographic ordering, i.e.:

$$f t > f u \text{ if } t \geq_{lex} u \text{ and } f t > u_i \text{ for all } i.$$

In that case, the Ackermann system is OK, since both $(sx, sy) \geq_{lex} (x, A(sx, y))$ and $A(sx, y) > A(sy, y)$ are true. For generalising this remark, one

can say that the problem is to take the necessary path ordering and to generalise it to vectors of terms (and this way of comparing vectors may depend upon the function symbol of which they are arguments).

For instance, we would like that $f t > f u$ if $t \geq_{lex} u$, and $g t > g u$ if $t \geq_{multiset} u$.

In order to say that, we can imagine that we have a functional on relations. Suppose \mathcal{E} is the set of terms, a functional on relations would be a function Δ from $\mathcal{L}(\mathcal{E})$ in $\mathcal{L}(\mathcal{E}^2)$. Suppose furthermore that Δ is a relation on terms, we write $\Delta \triangleright$ for the result of Δ to argument $>$. Examples of such a functional could be:

$$f t \triangleright f u \iff (t_1, t_2, \dots, t_n) \text{ lexicop. } (u_1, u_2, \dots, u_n)$$

$$g t \triangleright g u \iff (u_1, u_2, \dots, u_n) \text{ multiset } (t_1, t_2, \dots, t_n)$$

Now, we can induce some recursive partial orders as follows:

Definition 1. Suppose Δ an order (strict) on functions symbols. Then $t > u$ is defined inductively by the union of the following three cases:

- 1) $t = f t'$, $u = g u'$, $f \triangleright g$, $t' > u'$ for all i ,
- 2) $t = f t'$, $t' > u$ for some i ,

) ③

$$3) t = \tilde{f}t \Rightarrow f\tilde{t} = u, t >_i u \text{ for all } i.$$

Then, we can show that $>$ is a simplification as soon as the four following conditions on the functional \triangleright are true:

- a) \triangleright preserves transitivity,
- b) \triangleright preserves reflexivity,
- c) \triangleright is continuous (with respect to the subset topology)
- d) $t >_u$ implies $f(\dots t \dots) \triangleright f(\dots u \dots)$

Maybe condition (c) needs further explanations (and that's Sam who got the idea of continuity). That is a very weak condition. Let write $\triangleright_1 \subset \triangleright_2$ if the relation \triangleright_1 is contained in \triangleright_2 , i.e. $t >_1 u$ implies $t >_2 u$ for all terms t and u (as usual). Then \triangleright is continuous iff $t \triangleright u$ implies there is a finite subset of $>$, say $\triangleright \subset >$, such that $t \triangleright u$. That is that, in order to check $t \triangleright u$, one needs to look only at a finite number of pairs $t' > u'$. Conditions (a), (b), (c), (d) are surely true when:

$$\tilde{f}t = t \triangleright u = f\tilde{t} \quad \text{iff } \tilde{f} \triangleright_{\text{lexico}} u$$

$$\tilde{f}^0 = t \triangleright u = f\tilde{t} \quad \text{iff } \tilde{f}^0 \triangleright_{\text{multiset}} u = \{u_1, \dots, u_n\}$$

Conditions a, b, c are used for proving that $>$ defined by 1, 2, 3 is a strict order. Condition d is required for showing the monotonicity aspect of $>$ with respect to the structure of terms, i.e. $t > u \Rightarrow f(\dots t \dots) \triangleright f(\dots u \dots)$. It thus can be weakened to be true only when $>$ is the order \llcorner defined by 1-2-3.

The proof can be sketched by doing first some remarks in fixpoints. Suppose $\varepsilon(>_1, >_2)$ is the continuous functional corresponding to $t, 2, 3$. More precisely, $t = \tilde{f}t \varepsilon(>_1, >_2) \quad \tilde{g}u = u$

iff

- 1) $f \triangleright g$ and $t >_2 u$ for all i ,
- 2) $t_i \geq_i u$ for some i ,
- 3) $f = g$, $t >_1 u$ for all i and $t \geq_2 u$.

Then the wanted ordering is the least fixpoint of the functional $\lambda > \cdot \varepsilon(>, \triangleright)$, written $\mu > \cdot \varepsilon(>, \triangleright)$. Now (see Mann-Ness-Vaananen), since both \geq and \triangleright are continuous, one has:

$$\mu > \cdot \varepsilon(>, \triangleright) = \mu >_1 \cdot \mu >_2 \cdot \varepsilon(>_2, \triangleright_{>_1}).$$

In a less esoteric language, it means (using Kleene sequence) that the desired ordering \gg is the infinite union $(\gg^i)_{i=0}^\infty$ of orderings \gg^i such that: $\gg^0 = \emptyset$, $\gg^{i+1} = \mu > \cdot \varepsilon(>, \gg^i)$ for $i \geq 0$.

⑤

- Now, this means that \succ^{n+1} is defined inductively by:
 $t = f^T \succ^{n+1} g^T = u$ iff
 1) $f \succ g$ and $t \succ^{n+1} u$ for all i ,
 2) $t_i \geq_u u_i$ for some i ,
 3) $t \succ^n u$, $f = g$, $t \succ^{n+1} u_i$ for all i .

Now the proof is as follows:

Transitivity: $t \succ u \succ v$ implies $t \succ v$. It is sufficient to prove \succ^n transitive for all $n \geq 0$. Then, if $t \succ u \succ v$, $t \succ^n u \succ v$ for some $n, n \geq 0$. Therefore $t \succ u \succ v$ if $p = \max\{n, n\}$. And $t \succ^p v$. Thus $t \succ v$.

Therefore, we show \succ^n transitive. That is:

$t \succ^n u$ implies $t \succ^n v$ by induction on $\langle m, \|t\|, \|u\|, \|v\| \rangle$ ordered in lexicographic ordering. The case $n=0$ is trivial. Thus we try $n > 0$. There are 9 cases with respect to use of rules 1, 2, 3.

[1.1]: $t = f^T$, $u = g^T$, $v = h^T$ with $f \succ g$, $t \succ^n u$; for all i and $u > v$, for all j . Then $t \succ u \succ v$ and $t \succ^n v$.

For all i by induction. Since $f \succ g$, $t \succ v$ by rule 1.
 [1.2]: $t = f^T$, $u = g^T$ with $f \succ g$, $t \succ^n u$; for all i and $u_i \geq_v v$ for some j . Then $t \succ u \succ v$. Therefore $t \succ^n v$ by induction.

And so on ... until

[3.3] $t = f^T$, $u = g^T$, $v = h^T$ with $t \succ u$ for all i , $u \succ^n v$ for all i and $t \succ^{n+1} u \succ v$. By induction,

- we know that \succ^{n+1} is transitive. Thus, by condition (a) \triangleright^{n+1} is also transitive. Therefore $t \triangleright^{n+1} v$. Now $t \succ^n v$ for all i . Again by induction, $t \succ^n v$ for all i . Thus $t \succ^n v$ by rule 3. \square

Irreflexivity: It is again enough to prove \succ^n irreflexive for all n . Therefore by induction on $\langle n, \|t\| \rangle$. The case $n=0$ is obvious. Suppose now $t \succ^n t$. One has 3 cases:
 [1] $t = f^T \succ^n t = f^T$ by rule 1. Impossible, since \succ^n is irreflexive.

[2] $t = f^T \succ^n t$ since $t_i \geq_t^* t$ for some i . But $t \succ^n t$ also by rule 2. Therefore $t_i \succ^n t_i$ by transitivity. Impossible by induction.
 [3] $t = f^T \succ^n t = f^T$ since $t \succ^n t$ for all i and $t \triangleright^{n+1} t$. But \triangleright^{n+1} is irreflexive by induction. Therefore \triangleright^{n+1} is irreflexive by condition (b). This case is thus impossible. \square

Subexpression: $t \succ f(\dots \dots) \succ t$ by rule 2. \square

Monotonicity: Suppose $t \succ u$. Then $f(\dots \dots) \triangleright f(\dots \dots)$ by condition (a). Since $f(\dots \dots) \triangleright t_i$ for all arguments and $t \succ u$. Then $f(\dots \dots) \succ u$ by transitivity. Therefore $f(\dots \dots) \triangleright g(\dots \dots)$ by rule 3. \square

review plan: and 1 non-trans, Irreflex.

Now, there are funny examples of systems.

example 1: Ackermann (already done)

Then $A \triangleright s$ is the partial order on function

variables and

$$\begin{aligned} A(t, u) &\triangleright A(t', u') \text{ if } t > t' \text{ or } (t = t', u > u') \\ s \triangleright s' &\text{ if } t > t' \end{aligned}$$

Then

$A(sx, sy) > A(x, A(sx, y))$ by rule 3 if the following subgoals are true

a) $sx > x$ on by rule 2

b) $A(sx, sy) > x$ on since $A(sx, sy) > sx > x$.

c) $A(sx, sy) > A(sx, y)$ by rule 3 if again the subgoals:

- c1) $sy > y$ on rule 2
- c2) $A(sx, sy) > sx$ on rule 2.
- c3) $A(sx, sy) > y$ on rule 2 (twice).

Again:

$$A(sx, 0) > A(x, so)$$

since $A(sx, 0) > x$, $A(sx, 0) > so$, $sx > x$.

example 2: Group theory (Knuth-Bendix)

- 1: $(x \circ y) \circ z \rightarrow x \circ (y \circ z)$ (rule 3)
- 2: $x \circ x \rightarrow x$ (rule 2)
- 3: $\mathcal{I}(x) \circ x \rightarrow e$ (rule 1) with $\bullet \circ e$

- 4: $\mathcal{I}(x) \cdot (x \circ y) \rightarrow y$ (rule 1)
- 5: $x \cdot (\mathcal{I}(x) \circ y) \rightarrow y$ (rule 2)
- 6: $x \circ e \rightarrow x$ (rule 1)
- 7: $\mathcal{I}(e) \rightarrow e$ (rule 1)
- 8: $\mathcal{I}(\mathcal{I}(x)) \rightarrow x$ (rule 2)
- 9: $x \circ \mathcal{I}(x) \rightarrow e$ (rule 1)
- 10: $\mathcal{I}(x, y) \rightarrow \mathcal{I}(y) \circ \mathcal{I}(x)$ (rule 1 + 3) with $\mathcal{I} \circ \bullet$

The only interesting case is $(x \circ y) \circ z \rightarrow x \circ (y \circ z)$. This is due if $t \circ u \triangleright t' \circ u'$ when $t > t'$ or $(t = t', u > u')$ (left lexicographic ordering). Then it is sufficient to show

- a) $x \circ y > x$ (rule 2)
- b) $(x \circ y) \circ z > x$ (rule 2 - twice)
- c) $(x \circ y) \circ z > y \circ z$ (rule 3)

Again 3 subgoals:

- c1) $x \circ y > y$ on rule 2
- c2) $(x \circ y) \circ z > y$ (rule 2 - twice)
- c3) $(x \circ y) \circ z > z$ (rule 2).

Nice ?? Not ??

example 3: Some Alberto Pettorossi problem in combinatoric logic ("A property which guarantees termination in weak combinatory logic and subtree replacement systems")

II, Seta di Roma, Istituto di Automatico, R. 78-2
 Nov 78). In combinatory logic, the binary application operator $A(t, u)$ is not usually written. Thus the term means $A(t, u)$. More generally:

$t_1 u_1, \dots, t_n u_n$ means $A(\dots A(A(t_1, u_1), u_2), \dots, u_n)$

Alberto had the following property and could not prove it in its full generality.

Let \mathcal{C} be the set of combinatory logic terms.

Rules considered by Alberto are all of the form:

$$F x_1, \dots, x_n \rightarrow t \in \mathcal{C}_m$$

where F is a combination symbol, x_1, x_2, \dots, x_n are n distinct variables and \mathcal{C}_m is the subset of terms defined inductively by:

$$\mathcal{C}_0 = \emptyset, \quad \mathcal{C}_m = \{x_1, x_2, \dots, x_m\} \cup \{t u \mid t \in \mathcal{C}_{m-1}, u \in \mathcal{C}_m\}$$

As examples:

$$I x \rightarrow x \in \mathcal{C}_0$$

$$K xy \rightarrow x \in \mathcal{C}_1$$

$$B xyz \rightarrow z(yz)'' \in \mathcal{C}_2$$

$Sxyz \rightarrow (xz)(yz)$ is not OK, since z goes too far to the left of an application node. In fact, if $A = SSS$, one can show that AAA is not terminating.

Now, one can show in 5 lines that the Alberto conjecture is correct. (although not too much interesting from a programming point of view?)

One has just to take $t = t'$ if $t \neq t'$ and $t = t'$ and $t' = t'$. (In fact a stronger proposition may be shown by relaxing the construction of \mathcal{C}_n)

example 4: Plaisted (Sept 78) examples with the rules:

$$(x * y) * z \rightarrow x * (y * z)$$

$$x + (y + z) \rightarrow (x + y) + z$$

$$x * (y * z) \rightarrow (x * y) * z$$

Again lexicographic ordering (but right to left)

② QUASI-ORDERS ON FUNCTIONS SYMBOLS:

This is a very minor point. Instead of having an order \rightarrow on function symbols, one has a quasi-order. Rules are the same, except rule 3 which permits $f \stackrel{*}{=} g$ instead of $f = g$. This allows two function examples:

example 1: Mutual recursion.

$$g a \rightarrow a$$

$$g b \rightarrow b$$

$$f(x \cdot y) \rightarrow g x$$

$$g(x \cdot y) \rightarrow f y$$

Then $f \stackrel{*}{=} g$ is OK (\cong bullshit, but maybe interesting in practice).

5

Example 2: your FOCs example 3.

$$\begin{cases} \neg p \rightarrow p \\ \neg(p \vee q) \rightarrow \neg\neg p \wedge \neg\neg q \\ \neg(p \wedge q) \rightarrow \neg\neg p \vee \neg\neg q \end{cases}$$

Then $t \gg u$ iff $\llbracket t \rrbracket > \llbracket u \rrbracket$ or $(\llbracket t \rrbracket = \llbracket u \rrbracket \text{ and } \{t_1, \dots, t_n\} \supseteq \{u_1, \dots, u_m\})$. Let also make all the function symbols equivalent by \circ . (By $\llbracket t \rrbracket$ one means the number of symbols different from τ in t). Then one shows $t \gg u \Rightarrow \llbracket t \rrbracket > \llbracket u \rrbracket$. Thus $t \gg u$ implies $\{(\dots, t, \dots)\} \supset \{(\dots, u, \dots)\}$. Therefore condition (d) (the weak one) is true. (Remark that rule 1 never apply)

Therefore: $\neg\neg p > p$ by rule 2 (twice).

$\neg(\neg p \vee q) > \neg\neg p \wedge \neg\neg q$, by rule 3 since $\tau \models 1$ and $\llbracket \neg(\neg p \vee q) \rrbracket = \llbracket \neg\neg p \wedge \neg\neg q \rrbracket$, $p \vee q > \neg\neg p$ and $p \vee q > \neg\neg q$ and $\neg(\neg p \vee q) > \neg\neg p$, $\neg(\neg p \vee q) > \neg\neg q$ (easy). For instance, $p \vee q > \neg\neg p$ since $\tau \models \tau$ and $\llbracket p \vee q \rrbracket > \llbracket \neg\neg p \rrbracket$, $p \vee q > \neg\neg p$. Etc.....

③ CONCLUSION:

It seems also possible to work with quasi-simplifications by having two functionals (a reflexive one and an irreflexive one). But we have no

convincing examples here. The main trouble is that at the moment it is not possible to associate it to the quasi-simplification. The only gain could be writing a new weakening of condition b (d), which does not really need the strict ordering to be compatible with the structure, as you remember in your FOCs paper.

One short remark: (esoteric but which could impress all λ -calculus people). Can you prove termination of typed λ -calculus with simplifications? The Kruskal theorem must be true even with binders, and the usual Tait computability (see the Steinberg book) is short, but quite hard to understand. So maybe the argument can go through simplifications.

Some more sensible (?) remarks: Is it possible to leave simplifications and to get "semi-simplification". That is: the Kruskal theorem says that, in order, to show that the strict order $>$ is well-founded, it is sufficient to show that $\tau \gg \sigma = \neq$ (where \neq means in the embedding relation). But, as you remember in your proof of the Kruskal theorem, \neq is well-founded iff $\tau \gg \sigma$ is noetherian. Thus, one would like to have orderings $>$, which permits only finite chains such that $t_m > t_{m-1}$ and $t_m < t_{m+1}$ at the same time. For instance, the factorial function

terminates (via simplification) when it is written as following:

$$\begin{cases} f(sx) \rightarrow sx * f(x) \\ f 0 \rightarrow s0 \end{cases}$$

But, it is hard to believe that it is harder to prove the termination of factorial written as:

$$\begin{cases} f(sx) \rightarrow sx * f(p(sx)) \\ f 0 \rightarrow s0 \\ p sx \rightarrow x \end{cases}$$

Then $f(sx)$ is temporarily embedded in $f(psx)$. But this not too serious since $f(psx) \rightarrow fx$. For treating such an example, we would like to use the semantical fact that $[Isx] > [Psx] > [P]$. So the problem could be stated, as how to mix semantics and the syntactic recursive path ordering? If this is possible, it is not hard to believe that a more realistic version of factorial, namely

$$fx \rightarrow \underline{\text{if } x = 0 \text{ then } so \text{ else } x * f(px)}$$

could be proved to terminate. (with termination in the usual sense, i.e. evaluating the test of the conditional first).

5. Post-scriptum: mixing semantics and recursive paths orderings:

Assume that we have:

- (A) some well-founded ordering \triangleright on terms and \equiv some equivalence relation compatible with \triangleright , i.e.

$$\triangleright \stackrel{\text{subset inclusion}}{=} \triangleleft \quad \text{and} \quad \stackrel{\text{subset inclusion}}{=} \triangleright \triangleleft$$

- (B) some functional Δ on orders as previously with conditions:
- (a) preserving transitivity,
 - (b) " injectivity,
 - (c) continuity,
 - (d) monotonicity, i.e. $t \rightarrow u$ implies $f(\dots t \dots) \triangleright f(\dots u \dots)$

- (C) Δ contains the internal reduction \sqsupseteq relation, i.e.
- $t \rightarrow u$ implies $f(\dots t \dots) \Delta f(\dots u \dots)$.

Then consider the following definition of some "semantical" recursive path ordering, s.r.o. in short.

(15)

Definition of \Rightarrow : $t = \vec{f}t \Rightarrow \vec{g}\vec{u} = u$ iff

- 1) $t \triangleright u$ and $t \triangleright u_i$ for all i ,
- 2) $t_i \triangleright u$ for some i ,
- 3) $t = u$, $t \triangleright u$ and $t \triangleright u_i$ for all i .

Then one can show as previously, that \Rightarrow is a strict order, satisfying:

$$(a) -f(\dots t \dots) \triangleright t,$$

$$(b) -t \rightarrow u \text{ and } t \triangleright u \text{ implies } f(-\dots t \dots) \triangleright f(-\dots u \dots).$$

Thus \Rightarrow is not monotonic, but its intersection $\Rightarrow \cap \rightarrow$ with \rightarrow is. Therefore, rule (g) shows that, for testing that $t \triangleright u$ implies $t \triangleright u$, it is sufficient to test $\alpha_i \triangleright \beta_i$ for all instances α_i and β_i of left-hand sides and corresponding right-hand sides. So \Rightarrow may not be a simplification ordering.

Now, one can show that \Rightarrow is a well-founded ordering, provided some further condition is true on ordering, provided some further condition is true on

D:

- (g) For any infinite sequence $(t^i)_i$ such that $t^i \triangleright t^{i+1}$ for all $i \geq 0$, there is an infinite sequence $(u^i)_i$ such that, for all i , there is an argument $u_{k_i}^i$ of $u^i = f_i(u_1^i, \dots, u_p^i)$ satisfying
- $$u_{k_i}^i > u_{k_{i+1}}^{i+1}$$

(16)

This is not very nice (quite ugly in fact) and there is maybe one way of weakening it. Roughly speaking, it says that \Rightarrow preserves the noetherian aspect of \triangleright (in the arguments), but this is true when:

$$t = \vec{f}t \Rightarrow f\vec{u} = u \quad \text{if } \{\vec{t}_1, \dots, \vec{t}_n\} \text{ multiset } \{u_1, \dots, u_p\}.$$

Proof that \Rightarrow is well-founded: (As the Kruskal theorem)

Suppose \Rightarrow is not well-founded. We take a minimal counterexample: $t_1 \triangleright t_2 \triangleright t_3 \triangleright \dots \triangleright t_n \triangleright \dots$ (i.e., t_n is at each step minimal in size of all counterexamples starting with t_1, t_2, \dots, t_{n-1}). We remark first that rule 2 is never applied, otherwise this is not a minimal counterexample. Thus, only rules 1 and 3 are applied.

Now \Rightarrow is well-founded, thus after some while, only rule 3 is applied. But condition (g) tells us this is not possible. Because, since $t_m \triangleright t_{m+1} \triangleright t_{m+2} \triangleright \dots$ after some m , there is a subsequence of arguments $(u_{k_i}^i)$: by (g) such that $u_{k_i}^i > u_{k_{i+1}}^{i+1} > \dots$. Say that $u_{k_i}^i$ is an argument of t_m . Since $t_m > u_{k_i}^i$, the counterexample is not minimal, because $t_1 \triangleright t_2 \triangleright \dots \triangleright t_{n-1} \triangleright u_{k_i}^i > u_{k_{i+1}}^{i+1} > \dots$ is a "shorter" counterexample. Contradiction. \square .

(17) Now, let look at some examples. First, we want to follow Plaisted's idea. And say there is some partial ordering \geq on function symbols (strict-order for simplifying) and we also suppose that the ~~alphabet~~ function symbols alphabet is finite. (also for simplifying). Now, we consider some interpretation $\llbracket t \rrbracket$ of any term t , which satisfies the rewriting system. Thus:

(a) $t \rightarrow u$ implies $\llbracket t \rrbracket = \llbracket u \rrbracket$.

Finally, let $\llbracket \vec{t} \rrbracket$ be an abbreviation for the vector $(\llbracket t_1 \rrbracket, \llbracket t_2 \rrbracket, \dots, \llbracket t_n \rrbracket)$ of the semantics values of (t_1, t_2, \dots, t_n) . And suppose, we assume that we have some well-founded order \geq on vectors $\llbracket \vec{t} \rrbracket$. The well-founded ordering needed in the definition of s, r, p, o is done by stating:

(b) $\llbracket \vec{t} \rrbracket = t \Rightarrow u = g \vec{u}$ iff
either $f \odot g$
- or $f = g$ and $\llbracket \vec{t} \rrbracket \geq_s \llbracket \vec{u} \rrbracket$

(c) $\llbracket \vec{t} \rrbracket = t \Leftrightarrow u = g \vec{u}$ iff $f = g$ and $\llbracket \vec{t} \rrbracket =_s \llbracket \vec{u} \rrbracket$.

Since the interpretation makes valid the rewrite rules, it is straightforward to check that $t \rightarrow u$ implies $f(\dots t \dots) = f(\dots u \dots)$.

(18) It is maybe better to rewrite the definition of the new considered s, r, p, o .

Definition 2: $t = \llbracket \vec{t} \rrbracket > g \vec{u} = u$ iff
 ① $f \odot g$, and $t \geq_s u$ for all i ,
 ② $f = g$, and $\llbracket \vec{t} \rrbracket \geq_s \llbracket \vec{u} \rrbracket$, and $t \geq_u u$ for all i ,
 ③ $t_i \geq_u u$ for some i ,
 ④ $f = g$, and $\llbracket \vec{t} \rrbracket =_s \llbracket \vec{u} \rrbracket$, and $t \geq_u u$, and $t \geq_s u$ for all i .

Notice that the choice of \geq can be parameterised by the function symbol f . Similarly for \gg (in fact stronger: it may depend also on the equivalence class modulo the semantics equivalence). Consider next example:

example 1: Factorial:

$$\begin{cases} f(sx) \rightarrow sx * f(px) \\ f(0) \rightarrow s0 \\ psx \rightarrow x \end{cases}$$

Then, suppose $f \odot *$, $f \odot p$, $f \odot s$,
In order to show that $fx > px * f(px)$, by rule 1,
one has two sub goals:

$$\begin{aligned} fx &> px & (\text{true by rule } s) \\ fsx &> f(px) \end{aligned}$$

Now, we use the well-founded usual ordering on N , and we have $\llbracket sx \rrbracket \geq \llbracket px \rrbracket$. Therefore, by rule 2, we show $fsx > f(px)$, if $fsx > px$. But

β is more complicated than $P \circ (P \oplus P)$. Therefore, by rule 1, one has: $f(x) > s_x$ as subgoal, which is true by 3.

Now $f(0) > s_0$, since $f @ s$ and $f @ > 0$ by rule 3.

Finally $P \circ x > x$, since $s_x > x$ by rule 3 (trivial).

Some remarks: we use only the interpretation of P and s . Therefore, some possible interpretation could be:

$$\begin{aligned} \llbracket f t \rrbracket &= \llbracket f_1 \llbracket t \rrbracket \rrbracket = 1 \quad \text{for all } \llbracket t \rrbracket, \\ \llbracket t * u \rrbracket &= 1 \quad \text{for all } t, u, \\ \llbracket s t \rrbracket &= \llbracket t \rrbracket + 1, \quad \llbracket 0 \rrbracket = 0, \\ \llbracket p t \rrbracket &= \llbracket t \rrbracket - 1, \quad \llbracket t \rrbracket > 1 \\ \llbracket p o \rrbracket &= 4 \end{aligned}$$

Remark too that, in case the interpretation is the trivial one (everything equal). Then, definition 2 does no more than the usual (syntactic) recursive path ordering. And the trivial interpretation surely satisfies the rewriting rules. Thus, there can be some kind of training in defining the interpretation, taking care only of what is really needed in the termination proof. For instance, having not introduced at all $*$ and $+$, we can add all the axioms of the plain old's !

also by acting on \geq and $=_s$

paper (Sept 78) like:

$$x * (y * z) \rightarrow (x * y) * z, \dots$$

and keep the tally syntactic proof.

6- Post scriptum 2 : Used recursive programs with the conditional.

Now we want to consider the true factorial:
 $f(x) \rightarrow \begin{cases} x = 0 \text{ then } s_0 \\ x > 0 \text{ then } x * f(p x) \end{cases}$
 We can define the evaluation by rules of inference!

Axioms: $t = t' \rightarrow t \oplus t'$:

$$\left\{ \begin{array}{l} \text{rewrite rules cuteness.} \\ (\text{it, if we supposed to} \\ \text{be normal forms}) \end{array} \right.$$

Inference rules:

$$\begin{array}{c} (\exists) \frac{t \rightarrow u}{f(t) \rightarrow f(u)} \quad (\text{for all } f \neq \emptyset) \\ (\exists') \frac{t \rightarrow u}{f(\dots t \dots) \rightarrow f(\dots u \dots)} \\ (\exists'') \frac{P \rightarrow Q}{\text{if } P \text{ then } t \text{ else } u \rightarrow t \text{ else } u} \end{array}$$

Thus, the evaluation of the predicate part of the conditional is forced before evaluation of the alternatives. Now, you can guess how to change rules 1,2,3,4 and get the following definition:

For simplifying, we suppose the if function of the to be the least complicated. Furthermore, it will be easier to write $\lceil P \rceil = \text{true}$ implies $t > u$, as $P = t > u$. Similarly for $\lceil P \rceil \neq u$. Thus

Definition 3: We keep 1.2.3.4 when f and g are not if.
 We add $t = f \bar{E} > g \bar{u} = u$ if
 (A') $t \neq u$, $u = \lceil P \rceil \text{ then } u_1 \text{ else } u_2$, $t > P$, $P \models t > u_1$ and
 $\lceil P \rceil = t > u_2$,
 (3') $t = \lceil P \rceil \text{ then } t_1 \text{ else } t_2$, $P \geq u$ or $P \models t_1 > u$ or
 $\lceil P \rceil = t_2 \geq u$
 (4') $t = \lceil P \rceil \text{ then } t_1 \text{ else } t_2$, $u = \lceil q \rceil \text{ then } u_1 \text{ else } u_2$, $P > q$,
 $q \models t > u_2$, $\lceil q \rceil = t > u_2$.

Notice that, only in case (3'), there are disjunctions. All the rest are conjunctions. Now it is routine (?) to let that $>$ is still transitive, reflexive, well-founded and satisfying:

- (m) $\lceil P \rceil \text{ then } t_1 \text{ else } t_2 > P$
- (n) $P \models \lceil P \rceil \text{ then } t_1 \text{ else } t_2 > t_1$
- (o) $\lceil P \rceil \neq P \text{ then } t_1 \text{ else } t_2 > t_2$

Furthermore, the monotonicity rule is still true. In fact, a weakened version of it is true, but

sufficient for proving what is really needed (that is that showing $t > u$ for any instance of an axiom of the resulting system satisfies $t > u$ for all t and u). In other words, we want to validate the inference rules. Thus:

- rule I is still valid, using rule 2 of definition 3 (i.e. showing $t > u$ for any instance of an axiom of the resulting system satisfies $t > u$ for all t and u).
- rule II now: Suppose $P > q$ and $P > q$. Then we want to apply rule 4' in order to show that $t = \lceil P \rceil \text{ then } t_1 \text{ else } t_2 > u = \lceil q \rceil \text{ then } t_1 \text{ else } t_2$. Since $P > q$, we have $\lceil P \rceil = \lceil q \rceil$. Thus $\lceil P \rceil = \text{true}$ iff $\lceil q \rceil = \text{true}$. By rule 3', we know that $P \models t > t_1$ and $\lceil P \rceil \models t > t_2$. Therefore $q \models t > t_1$ and $\lceil q \rceil \models t > t_2$. And rule 4' permits now $t > u$.

example 1: factorial

$$\begin{cases} f(x) \rightarrow \text{if } x=0 \text{ then } s \\ p \models x \rightarrow x \end{cases}$$

Then $p \models x > x$ by rule 3 (twice). Now, we have to show $f(x) > \text{if } x=0 \text{ then } s \text{ else } x * f(p \cdot x)$. We try rule 1'. Therefore, we have three subgoals.

- 1) $f(x) > x = 0$. Ok if $f(0) = s$ and $f \odot 0$.
- 2) $f(x) > s = 0$. I don't.
- 3) $x \neq 0 \models f(x) > x * f(p \cdot x)$.

(23) we come back to the method of page 18. By interpreting correctly p and s and taking the well-founded order in order on integers. Notice that we need to interpret also the test for zero.

Example 2 : The 91-function:

$$g(x) \rightarrow \text{if } x > 100 \text{ then } x-10 \text{ else } g(g(x+11))$$

Here there is a big trouble for making a difference between the recursive path ordering $>$ and the symbol $>$ of $x > 100$. We do as for factorable, but we need more information on a possible interpretation of satisfying the recursive system. Take for interpreting f , the function $f(x) = \text{if } x > 100 \text{ then } x-10 \text{ else } g_1$ (which is one solution - Remark that we do not know if it is the solution). Then the proof is as for factorial, generalizing at some points:

$$x \leq 100 \vdash x \geq g(g(x+11)) \quad \& \quad x \geq x+11$$

which is on for finding some well-founded order \geq i.e. $x \geq y$ when $x \leq y \leq 111$ (as in your paper with Zohar Mannan on multisets for proving termination).

I agree there is nothing new under the sun (as we say here). But what is maybe interesting is the ability of mixing syntax and semantics ?? And the |

learning between the next recursive path ordering and some cut points workflow ?? Although I can't draw of examples.

Finally, & there is some mistake (which makes applying these post-scriptum), do not change Sam's responsible who left mainland for the PCPL conference. But that's (I believe) what we try to do before he left. Also, do we reproduce this too much until it could get worse before Jesus. Copies are also sent to Henk Barendregt, Gerard Berry, Leo Bubas, Jan-Willem Klop, Gerard Huet, Gordon Plotkin who could also be interested by that.

Appendix to the 1st Folio note:

1.5: On functionals of orderings:

In order to make possible \triangleright for the multiset ordering (page 3), one has to merge conditions a & b in:

(a') \triangleright preserves strict orderings

(otherwise the multiset functional does not preserve reflexivity by itself.) The proof still works, but with a parallel induction for proving transitivity and irreflexivity at same time.

a well-ordering \triangleright^t with $t \leq u$ = being an equivalence compatible with it. Now as \triangleright^t is a well-ordering, by the Kruskal theorem, its free image is a well-partial ordering, i.e., in any infinite sequence $(t_i)_i$ of terms there is a pair t_i and t_j with $i < j$ such that $t_i \leq t_j$, where true is true iff:

- (1) $u = \hat{g}^t u$ and $t \leq u$ for some i ,
- (2) or $t \leq u$ and $t_i \leq u_i$ for all i with $1 \leq k_1 < k_2 < \dots < k_m$.

Now, consider the s.r.p.o induced by \triangleright^t following definition of page 15), i.e., $t = \hat{g}^t u = u$ iff:

- (1) $t \leq u$ and $t \leq u_i$ for all i ,
- (2) $t_i \leq u$ for some i ,
- (3) $t \leq u$, $t \triangleright^t u$ and $t \triangleright^t u_i$ for all i .

Then again the s.r.p.o \triangleright^t is a strict ordering (same proof) and contains the s.r.p.o \triangleright defined with the well-founded partial ordering \triangleright . If one shows that \triangleright^t is well-founded, we have then showed that \triangleright is also well-founded and then finished. But \triangleright^t is surely well-founded, since in any infinite sequence $(t_i)_i$ of terms, there is $t_i \leq t_j$. But then $t \leq u$, because \rightarrow is contained in \leq with $t_i \leq t_j$ and $t_i \leq t_j$ are not possible at same-time.
